Abstract

Thermal measurements on a GaAs/AlGaAs heterostructure reveal that the state of the confined two-dimensional electrons dramatically affects the nuclear-spin diffusion near Landau level filling factor ν=1. The experiments provide quantitative evidence that the sharp peak in the temperature dependence of heat capacity near ν=1 is due to an enhanced nuclear-spin diffusion from the GaAs quantum wells into the AlGaAs barriers. We discuss the physical origin of this enhancement in terms the possible Skyrme solid-liquid phase transition.

In the presence of a perpendicular magnetic field (B), two-dimensional electron systems (2DESs) exhibit striking phenomena originating from the Landau quantization and electron-electron interaction; examples are the integral and fractional quantum Hall effects [1]. At Landau level filling factor ν=1, theoretical work on 2DESs in GaAs/AlGaAs heterostructures has shown that electron spin textures known as *Skyrmions* are the lowest energy, charged excitations of the ferromagnetic ground state [2]. Skyrmions, which result from the dominance of the electron-electron exchange energy over the Zeeman energy, are also the lowest energy state for quasi-holes and quasi-electrons *near* ν=1; the ground state of a 2DES near ν=1 is in fact expected to be a *crystal* of Skyrmions [3–5].

Recent experimental studies have revealed that Skyrmions play a major role in many properties of quantum Hall systems [6–9]. In particular, measurements on a GaAs/AlGaAs multiple-quantum-well (QW) heterostructure indicated an anomalous behavior for the low-temperature apparent-heat-capacity (C) near ν=1: C is enhanced by a factor of up to $\sim 10^5$ with respect to its low-B value [9]. For temperatures $T \gtrsim 0.1$K, the magnitude as well as T- and B-dependence of the data are consistent with the large C being dominated by the Schottky nuclear heat capacity of Ga and As atoms in the QWs. This observation implies a strong enhancement of the nuclear spin-lattice relaxation rate near ν=1, consistent with the results of nuclear magnetic resonance (NMR) experiments [6,7] and recent calculations [5] which attribute the enhancement to the presence of low-energy spin-flip excitations in the 2DES. An even more striking feature of the C vs T data is a very sharp peak at a very low temperature $T_c(\nu)$, suggestive of a phase transition in the 2DES [9]. While recent estimates for the melting temperature of the Skyrme crystal [4,5], including its dependence on ν, suggest that the peak in C could originate from a Skyrme solid-liquid phase transition, the physical mechanism that affects the nuclear spin dynamics and gives rise to the anomalous C-peak is not known and is a matter of debate [4,5,9].

In this Letter we report new quasi-adiabatic thermal experiments revealing that the mechanism responsible for the peak in C vs T is a dramatic enhancement of nuclear spin diffusion across the QW-barrier interface. While only the nuclear heat capacity of the QWs'

atoms is observed away from T_c, the nuclei in both the QWs and barriers contribute to the measured heat capacity near T_c. We discuss the physical origin of this phenomenon in terms of the possible Skyrme solid-liquid phase transition.

The experiments were performed on the same multiple-QW heterostructure used in Ref. [9]. It consists of 100 GaAs QWs separated by $Al_{0.3}Ga_{0.7}As$ barriers. The wells and barriers are 250 and 1850Å thick, respectively, and the barriers are δ doped with donors (Si) near their centers. We used a $7 \times 7 mm^2$ piece of the wafer which was thinned to 65μm. The lattice T is probed by a carbon paint resistor deposited on the substrate side of the sample and electrically connected with four very low thermal conductance, 8μm-diameter, NbTi wires. This resistor was calibrated against a RuO_2 resistance thermometer at B=0. Since the nuclear spin temperature (T_N) may be inhomogeneous in the sample due to a variable nuclear spin-lattice relaxation rate [6], T strictly refers to the measured *lattice* temperature. The sample is supported by two 60μm-diameter NbTi wire which serves as the main weak thermal link to the cold finger of the dilution refrigerator mixing chamber. In the restricted T and ν-range investigated here, C is very large and the observed external time constant, τ_{ext}, reaches extremely large values which exceed 10^4 seconds. Therefore, in the time scale of our experiments, which is governed by the observed internal time constant $\tau_{int} \sim 10^3$ s (see below), the sample is in the quasi-adiabatic regime. B is applied at an angle of $\theta = 30^\circ$ with respect to the 2DES plane in order to match the experimental conditions of Ref. [9].

We first summarize the heat capacity results of Ref. [9]. Figure 1 shows the measured C vs T at ν=0.77, revealing a sharp peak at T_c=42mK. While at high T ($\gtrsim$70mK) the measured value and T-dependence of C are rather consistent with the calculated Schottky nuclear heat capacity of Ga and As atoms in the QWs [9,10] (solid curve in Fig. 1), at lower T, and especially near T_c, C exceeds the calculated value by a factor of up to $\sim$10. The peak value of C, however, appears consistent with the Schottky nuclear heat capacity of the heterostructure if the nuclei of the *barrier* atoms are also included (dotted curve in Fig. 1). This observation suggests that, near T_c, the barriers' nuclear spins also contribute to the measured C.

In our new quasi-adiabatic experiments, we utilize another noteworthy feature of the heat capacity data; as seen in Fig. 1 inset, T_c sensitively depends on filling factor. This dependence, which is reproduced in Fig. 2 (a) (dashed curve), is the key to understanding our results. In these experiments, we first fix the magnetic field at B=8.5T (ν=0.77) where the peak in C occurs at T_c=42mK (Fig. 1 and dashed curve in Fig. 2(a)). Starting from $T\sim$60mK, we cool down the cold finger to base temperature ($\sim$10mK) and the lattice slowly cools down to $T\sim$32mK by waiting for about 50 hours. Then, in order to further improve the adiabatic conditions, the weak heat flow that results from the T-difference between the lattice and the cold finger is reduced by increasing the cold finger temperature to 32$\pm$3mK. Under these conditions, we observe that the measured sample T is stable within the experimental accuracy ($\lesssim \pm$0.2mK) over periods longer than τ_{ext}, meaning that the sample is effectively quasi-adiabatic.

In a first experiment, whose results are shown by open circles in Fig. 2(a), we started from such a quasi-adiabatic condition and swept B from 8.5 to 7.7T, at a rate of 0.01 T/minute. We observe that T rises from 31.7mK to 36.2mK. B was then swept back to 8.5T at the same rate; this led to a rise of T to 39.5mK. While the increase in T with increasing B may be explained by the adiabatic magnetization of the nuclei in the QWs, which couple to the lattice, according to [10]:

$$T_N \propto B, \tag{1}$$

the T rise observed when B is *lowered* from 8.5T to 7.7T is puzzling.

In order to better understand the results of the above experiment, we performed a similar experiment, starting from T=32.6mK, but here we swept B in steps of 0.2T from 8.5T to 7.3T, with a hold time of 3 hours between steps. The evolution of T during this second experiment is presented in Fig. 2(b) and summarized in Fig. 2(a) by close circles. We note that in each step, except for steps 2$\rightarrow$3 and 3$\rightarrow$4, the lattice T rises during the B-sweeps and then decays to approximately the same value as the one at the end of the previous step. These T rises are due to Eddy-current heating of the 2DES and the lattice during

the B-sweeps. The heat is evidently slowly absorbed by the nuclei during and following the sweep via internal relaxation. Because of the very large heat capacity of the nuclear spins, this (Eddy-current) heating does not lead to an appreciable increase in the lattice T at the end of the step [11]. The key feature of this experiment, however, is that during the 2→3 and 3→4 steps, the lattice T increases significantly while the sample is in quasi-adiabatic conditions. Note in particular that, during the 2→3 step, the lattice T rises even *after* the B-sweep is completed. This striking behavior occurs when the lattice T approaches T_c at which C exhibits a maximum (dashed curve in Fig. 2(a)). Indeed, it appears that near T_c *the lattice is heated internally*.

To explain the results of Figs. 1 and 2, we propose a model in which the barriers' nuclei couple to the QWs' nuclei very near T_c, but decouple at higher and lower temperatures. The sharpness of the peak in C vs T data (Fig. 1) is consistent with this model and implies that the coupling between the QWs and barriers is turned off rapidly as T deviates from T_c. Therefore, we expect that during the initial cool-down at B=8.5T, when T decreases below T_c=42mK, T_N in the AlGaAs barriers remains close to 42mK while T_N of the QWs decreases down to ≈32mK due to strong coupling to the lattice. Next, decreasing B below 8.5T (steps 1→7) in adiabatic conditions has two distinct consequences: (1) T_N in both the QWs and barriers is reduced due to adiabatic demagnetization of the nuclei (Eq. 1), and (2) the coupling between the QWs and the barriers will increase dramatically when the dashed (T_c vs B) curve in Fig. 2(a) is crossed. While the former is essentially monotonic in B, the latter is not and implies that, near the dashed curve in Fig. 2(a), T_N should equalize over the whole GaAs/AlGaAs heterostructure. Since the barriers' nuclei were initially warmer than the QWs' nuclei, we expect a rise in lattice T near this crossing, as observed experimentally. Finally, we attribute the T rise during the final (7→8) step to the nuclear magnetization of the nuclei (Eq. 1).

Beyond the good qualitative description of the experiments in Fig. 2, the above model appears to provide a reasonable quantitative account of the data also. First, when B is lowered from 8.5T to 7.3T, we expect from Eq. 1 that nuclear demagnetization reduces T_N

in the barriers from ≈42mK to ≈36mK. Since the barriers are by far thicker than the QWs, according to our model, this value should approximately correspond to the temperature of the entire heterostructure, and hence of the lattice. This prediction is in good agreement with experiments that give T≈37mK at B=7.3T. The final increase of T from ≈37mK to ≈43mK when B increases from 7.3T to 8.5T is consistent with the nuclear magnetization of the heterostructure (Eq. 1). Second, the fact that, at T_c, C reaches the value expected for the entire heterostructure (dotted curve in Fig. 1) is clearly consistent with our model and hence provides additional credence to our interpretation.

Next, we discuss the internal time constant (τ_{int}) observed in our experiments. Figure 3 presents a typical heat pulse/relaxation trace, in quasi-adiabatic conditions, obtained during heat capacity experiments near T_c. The relaxation follows an exponential decay characterized by τ_{int}. The inset to Fig. 3 shows that τ_{int} exhibits two different, but remarkably constant, values above and below 30mK: ∼1600s and ∼900s, respectively. We note that this crossover temperature corresponds to the T below which C is reduced back to a value close to the nuclear heat capacity of the 100-QWs, C_{QW} (full curve in Fig. 1).

In order to explain these observations, we consider three possible mechanisms responsible for the observed τ_{int}. Heat diffusion in the nuclear spin system of the barriers is governed by the one-dimensional diffusion equation:

$$\frac{\partial T}{\partial t} = D\frac{\partial^2 T}{\partial z^2} \tag{2}$$

where $D \sim 10^{-17}\mathrm{m}^2/\mathrm{s}$ is the nuclear-spin diffusion constant in GaAs [12] and the z-axis is along the growth direction. Therefore, it gives an internal time constant:

$$\tau_d \sim \frac{r^2}{D} \tag{3}$$

where r is the distance over which diffusion takes place [13]. Since each barrier is surrounded by two QWs, we take r=925Å (half the barrier thickness) and Eq. 3 gives τ_d∼800s. The two other mechanisms involved in the heat transfer from the lattice to the barrier nuclei, i.e. nuclear spin-lattice relaxation in the QWs and diffusion across the QW-barrier interfaces, result in two additional time constants: T_1 and τ_i, respectively. When $C \approx C_{QW}$ ($T \lesssim 30$mK),

the diffusion across the QW-barrier interface is negligible and τ_{int} should be determined by T_1 only. On the other hand, when $C > C_{QW}$ ($30 \lesssim T \lesssim 50$mK) at least a fraction of the barriers' nuclei couple to the QWs' nuclei. This implies that τ_d and τ_i should *increase* τ_{int}. This is consistent with the rise in τ_{int} observed above 30mK (Fig. 3 inset). Moreover, we note that the increase of τ_{int} above 30mK ($\sim$700s) is comparable to the estimated $\tau_d \sim$800s, implying that τ_i is rather small once the barrier nuclei do couple to those in the QWs [14].

We now remark on the physical origin of the peak in C vs T. NMR experiments show that nuclear spin-diffusion from the QWs into the barriers is extremely weak, except when optical pumping broadens the Knight shift peak of the QWs which then overlaps with the NMR peak of the barriers [6]. The spectral overlap allows spin-diffusion which is driven by nuclear magnetic dipole-dipole coupling [6,15]. Therefore, the enhancement of spin-diffusion across the QW-barrier interface near T_c could originate from a broadening of the Knight shift peak in the QWs. In the liquid Skyrme phase, motional averaging of the local 2DES spin polarization produces a single Knight shift peak [3,7]. On the other hand, the absence of motional averaging in the solid Skyrme phase should induce both positive and negative Knight shifts depending on the *local* spin polarization of the 2DES. Since above and below the peak in C vs T the diffusion across the QW-barrier interface is very weak, this implies that in both the liquid *and* the solid Skyrme states, the Knight shift peak(s) do not overlap with the NMR peak of the barrier. One possible explanation for the C anomaly is that the critical slowing down of the spin fluctuations in the 2DES, associated with the Skyrme liquid-solid phase transition [5], could induce a broadening of the Knight shift peak in the QWs. This broadening would induce spectral overlap of the QWs' and barriers' NMR peaks and hence allow spin-diffusion across the QW-barrier interface *only* near T_c.

Finally, it is worth emphasizing that the shape of the peak in C vs T points to a second-order phase transition [16]. The fact that τ_{int} is constant in the T-range where $C > C_{QW}$ near T_c implies that the *strength* of the coupling to the barriers remains constant while C varies strongly. Therefore, it appears that the smaller value of C on the sides of the peak in C vs T comes from a *reduced fraction* of the sample in which the barriers' nuclei couple to

the QWs' nuclei. The complexity of spin textures in the 2DES, together with the fact that the phase transition is not observed directly but through its effect on nuclear-spin lattice relaxation, does not allow a quantitative analysis of the data in the framework of the existing theories that describe order-disorder phase transitions. On the other hand, Skyrmions form an XY ferromagnet which has broken translation symmetry and one expects at least one phase transition as T is lowered [5].

In conclusion, our experiments reveal the critical influence of the ground and excited states of the 2DES near ν=1 on nuclear-spin dynamics in GaAs/AlGaAs heterostructures. Our results provide a quantitative phenomenological description of the apparent heat capacity anomaly that may originate from a Skyrme solid-liquid phase transition.

[11] Complementary experiments allow us to estimate the T increase expected from the Eddy-current heating during the B-sweeps. Our estimate is $\lesssim$2mK for the *total* T rise during steps 1 to 8. This may explain the slightly larger T ($\approx$43 mK) measured at the end of step 8 compared to the starting barrier T_N which is expected to be $\approx$42 mK according to our model.

[12] D. Paget, Phys. Rev. B **25**, 4444 (1982). In our estimate here, we use D for GaAs since D for $Al_{0.3}Ga_{0.7}As$ is not known.

[13] See e.g. R.P. Tye, *Thermal conductivity*, (Academic Press, London, 1969) p. 168. Note that the actual boundary conditions used to solve Eq. 2 may add a prefactor to the right term of Eq. 3 which gives only a rough estimation of τ_d.

[14] It is worth remarking that the parts of the sample for which $\tau_d \gg \tau_{ext}$ do not contribute to the measured C in the T and B range we are discussing. Since $\tau_d \gtrsim 10^5$ s for $r > 10^{-6}$ m (Eq. 3), the GaAs substrate contributes negligibly to C.
